#### Abstract

: Many Chinook salmon in the Kuskokwim River are harvested using "large mesh" (8 inches or larger) gillnets that preferentially capture older and larger fish. There is interest in determining if this selective fishery has a population-level impact on traits such as adult size and age. To evaluate this issue estimates of trait heritability are needed. Although heritability estimates are available from hatchery populations in the Pacific Northwest these estimates may not reflect the variety of environmental conditions that influence trait variation in wild Chinook salmon populations in western Alaska. In this study we used genetic markers to reconstruct a partial two-generation pedigree from a wild Chinook salmon population in the Tuluksak River. The inferred parent-offspring relationships, combined with phenotypic data on adult size (length) and age-at-maturity provide the first estimates of the heritability of these traits in western Alaska salmon. These estimates of heritability ( 0.240 and 0.238 for adult length and age-at-maturation, respectively) indicate both traits have detectable genetic variation in this population although the values are lower than those reported for a hatchery population of Chinook salmon in Puget Sound, Washington. While we could not conclude that these heritability estimates are significantly lower than those reported for the hatchery population, these new values do provide locally derived estimates from a wild population to use in future studies on the influence of gear selectivity. Because the reconstructed pedigree was smaller than expected, we were unable to estimate the genetic covariance among these traits or evaluate gender-specific heritability. The pedigree was also used to evaluate variation in family size however due to the small size of the pedigree the results were not conclusive. Given the value but very limited amount of information on heritability and family size variation in wild salmon populations, and the availability of weirs on some tributaries of the Kuskokwim River, we feel further work that builds on the results of this study should be pursued.

Key Words: heritability, pedigree, Chinook salmon, age-at-maturity, length, reproductive success, Kuskokwim River, Tuluksak River, western Alaska

## LIST OF FIGURES:

Figure 1. Map of the Tuluksak River showing the past and present weir sites.12

Figure 2. MCMC estimates of heritability of length (mid-eye to fork of caudal fin, MEF) for Tuluksak River Chinook salmon. The left panel shows the trace of the estimate of heritability for the fitted model plotted over the 2,300,000 iterations of the MCMC chain. The right panel shows the posterior density of the estimate of heritability for the fitted model.

Figure 3. MCMC estimates of heritability of age-at-maturation for Tuluksak River Chinook salmon. The left panel shows the trace of the estimate of heritability for the fitted model plotted over the $2,300,000$ iterations of the MCMC chain. The right panel shows the posterior density of the estimate of heritability for the fitted model.

Figure 4. The observed and expected distribution of the number of adult offspring for 53 female Chinook salmon sampled from the Tuluksak River in 2003.

## LIST OF TABLES:

Table 1. Sample summary for Tuluksak River Chinook salmon (2003, 2007-2009). Pre-spawn and post-spawn samples were taken at and above the weir, respectively. The column "2003 cohort analyzed" include only individuals from the 2003 cohort sample that were genotyped for 14 or more loci
Table 2. Estimated number of alleles (A) and heterozygosity ( He ) for 17 microsatellite loci in Tuluksak River Chinook salmon. These estimates were derived using the 309 samples from the 2003 cohort and the 108 samples from the 2003 adult return.
Table 3. Average length (avgL, mid-eye to the fork of the caudal fin) in mm and standard deviation by age and sex for adult Chinook salmon from the Tuluksak River used in this study. The parent group returned in 2003 and the offspring group (progeny from the 2003 adults) returned in 2007-2009.
Table 4. Reconstructed pedigree for adult Chinook salmon that returned to the Tuluksak River in 2003 and their adult offspring that returned in 2007, 2008, and 2009. The pedigree was generated using the computer program FRANz. Year of return for each sample is denoted by the first two numbers following "ktul". The asterisk denotes the offspring for which both a male and female parent were identified. Phenotypic data for parents and offspring can be found in Appendices 1 and 2.
Table 5. Heritability estimates for length (mid-eye to fork of caudal fin, MEF) and age-atmaturation for Tuluksak River Chinook salmon.19

Table 6. The number of Tuluksak Chinook salmon offspring from the 2003 cohort assigned to a sample of candidate parents ( 53 females, 55 males) from the 2003 adult return.22

Table 7. The index of variability $R_{k}=(v(k) /(\bar{k}))$ of family size for the sample of candidate parents from the 2003 adult return of Tuluksak River Chinook salmon. $\bar{k}$ and $v(k)$ are the mean and variance of family size.

## LIST OF APPENDICES:

Appendix 1. Sample data for the 2003 cohort. MEF and MEH are the length estimates to nearest 5 mm from the mid-eye to the fork of the caudal fin (MEF) and from the mid-eye to hypural plate (MEH). Freshwater (FW) and saltwater (SW) age were derived from scales (live samples) or otoliths (carcasses).32

Appendix 2. Sample data for the candidate parents from the 2003 adult return. MEF is the length estimate to nearest 5 mm from the mid-eye to the fork of the caudal fin. Freshwater (FW) and saltwater (SW) age were derived from scales.

## INTRODUCTION:

Chinook salmon (Oncorhynchus tshawytscha) returning to tributaries of the Kuskokwim River in western Alaska are intercepted by both commercial and subsistence gillnet fisheries. Most of the fish are harvested in the subsistence fishery using "large mesh" (8 inches or larger) gillnets (Molyneaux et al. 2005). The large mesh nets avoid unintentional harvest of smaller more abundant species (e.g. chum salmon, O. keta) but also preferentially capture older and larger Chinook salmon (Molyneaux et al. 2005). There is interest in determining if (and to what extent) selective fisheries such as that targeting Kuskokwim River Chinook salmon have a populationlevel impact on traits such as mean adult size, age structure and growth rate (Molyneaux et al. 2005; AYK SSI 2006). The selective harvest of large adults may also indirectly impact population abundance if, for example, family size (number of adult progeny) is not randomly distributed in the population and is correlated with the size of parents. In order to evaluate these issues estimates of trait heritability and family size for a sample of parents of known length are needed. Ideally, estimates of heritability and family size would come from wild populations in western Alaska and would be derived with minimal experimental intervention (i.e. without controlled mating, hatchery incubation, and rearing). Presently, no such estimates are available. Empirical and modeling studies have shown that salmon fisheries have the potential to alter the genetic and phenotypic diversity of traits such as adult size (e.g. Hard 2004). Gillnet fisheries in particular may target fish of a certain size range which could result in directional or disruptive selection on size and traits often correlated with size (e.g. growth rate, age-at-maturity). Hamon et al. (2000) found that size selection in a gillnet fishery for sockeye salmon (O. nerka) likely caused directional selection on body size and shape within populations of a single age class but also caused disruptive selection on age structure in populations where age-at-maturity varied. Modeling studies have shown that a size-selective harvest could reduce size in Chinook salmon but that the level of influence would depend upon a number of factors including the heritability of size and correlated traits (Hard 2004; Bromaghin et al. 2011).

Heritability reflects the potential for a trait to evolve from selection. It also expresses the extent to which a given phenotype is determined by parental genes and thus will determine the degree of
phenotypic similarity between related individuals. In a narrow sense, heritability $\left(h^{2}\right)$ is the proportion of the total within population phenotypic variance $\left(V_{\mathrm{P}}\right)$ that is additive genetic $\left(V_{\mathrm{A}}\right)$ such that $h^{2}=V_{\mathrm{A}} / V_{\mathrm{P}}$ and $0 \leq h^{2} \geq 1$ (Falconer and Mackay 1996). Some estimates of heritability have been derived for adult size and associated traits in Pacific salmon. It is unclear, however, how broadly these estimates apply among species and populations that exhibit different size distributions and age structure and experience different environments that likely impart different selection regimes. For example, Smoker et al. (1994) and Funk et al. (2005) reported estimates of $h^{2}$ of 0.80 and 0.45 , respectively, for adult length in male pink salmon (O. gorbuscha) from different regions in Alaska. Regarding Chinook salmon, Hard (2004) has derived estimates of $h^{2}$ for adult length, age, and growth rate of $0.34,0.35$, and 0.31 respectively. However, because these values were derived from a hatchery population in Puget Sound, Washington, they may not reflect heritability in natural Chinook salmon populations in Western Alaska. Indeed, most studies of heritability in salmon have used a controlled mating experiment requiring some artificial incubation and hatchery rearing (but see Dickerson et al. 2005). These studies probably do not reflect the variety of environmental conditions that could influence phenotypic variation in wild populations (e.g. Coyne and Beecham 1989).

Most studies of family size and reproductive success in salmon have also relied on controlled mating and hatchery incubation with some rearing (e.g. Geiger et al. 1997; Hedrick et al. 2000). Nevertheless, the results from these studies suggest that the variation in family size in Pacific salmon populations is probably not random (does not follow a Poisson distribution, Frankham et al. 2002) and that a few parents contribute a disproportional number of progeny to each generation. Non-random variance in family survival could result from non-genetic factors such as flooding but may also have a genetic basis. Geiger et al. (1997) inferred a genetic component to marine survival in pink salmon by comparing family size in full-sib and half-sib groups from a controlled mating experiment. They deduced that the favored phenotypes must vary across generations but did not explicitly examine this issue. In a study of Chinook salmon mortality resulting from a natural bloom of toxic marine algae, Hard et al. (2000) found that non-random mortality among half- and full-sib families ( $8.3 \%$ and $12.7 \%$, respectively), was non-random and higher than that in the aggregate population (7.2\%), indicating that the mortality of the fish associated with the bloom was influenced genetically. The non-random mortality reflected a
modest estimate of heritability of mortality (0.15) based on a liability threshold model, and a corresponding reduction in effective population size of 9.4\%. Mean half-sib family size declined from 52.0 to 48.2 fish as a result of the bloom, and mean full-sib family size declined from 16.3 to 15.1 fish. The coefficient of variation for half-sib family size increased from 0.33 to 0.34 , and that for full-sib family size increased from 0.36 to $0 \cdot 38$. Seamons et al. (2004) and McLean et al. (2004) examined reproductive success in wild steelhead (O. mykiss) by reconstructing pedigrees of naturally spawning adults using molecular genetic markers. Seamons et al. (2004) found a positive but weak association between female size and reproductive success while McLean et al. (2004) found no association between adult size and progeny number.

In this study we will address three questions related to evaluating the impact of a size selective fishery on Chinook salmon in the Kuskokwim River. First, how heritable is adult size (length) and traits that may be correlated with adult size (growth rate, age-at-maturation) in males and females? Second, is variance in family size random? Third, if variance in family size is not random, is it related to size of the adult parent? We will study adult Chinook salmon from the Tuluksak River, a tributary of the lower Kuskokwim River (Figure 1). Molecular genetic markers (microsatellites) and recently developed statistical methods will be used to identify a pedigree consisting of adult progeny from the 2003 cohort (adults born in 2003) and their parents from the 2003 adult return. The reconstructed pedigree will be used to estimate heritability of adult size (length), growth rate, and age-at-maturation, and the level of genetic correlation among these traits in males and females. In addition, the pedigree will be used to evaluate family size. The 2003 cohort will be sampled over a three year period (2007-2009) because most adults mature in 4 to 6 years. By sampling the adults in the Tuluksak River, the heritability estimates will reflect lifetime selection just prior to spawning.

## OBJECTIVES:

Objective 1. Estimate the heritability of adult size (length), growth rate, and age-at-maturation and the genetic covariance among these traits, in male and female Chinook salmon from the Tuluksak River.

We were able to identify for the first time and with a relatively high level of statistical certainty a partial two-generation pedigree for wild Chinook salmon from the Tuluksak River. Using the inferred pedigree combined with the phenotypic data we obtained for the first time estimates of heritability for adult length (0.240) and age-at-maturation (0.238) in wild Chinook salmon from a western Alaska population. However, because the reconstructed pedigree was smaller than expected we were unable to assess growth rate, the genetic covariance among traits, and gender differences in heritability. We attempted to improve the pedigree by rerunning samples that did not provide adequate genotype information and by attempting additional statistical analyses. However, the results did not change. We concluded that a larger pedigree will be needed to completely address objective one.

## Objective 2. Determine if the variation in family size of Tuluksak River Chinook salmon is

 random, and if not, determine if family size is related to size of adult parent.The results of the evaluation of variation in family size were equivocal and thus we concluded there was not sufficient evidence to suggest family size variation in Tuluksak Chinook salmon is non-random. These results did not support evaluating if family size is related to the size of the adult parent. As with the analysis of heritability, we feel the lack of clarity in the evaluation of family size is due to the limitations of the small pedigree.

## METHODS:

## Study Area

The Tuluksak River is one of several tributaries flowing into the lower Kuskokwim River and is located approximately 116 rkm northeast of Bethel, AK (Whitmore et al. 2005). The Tuluksak River is approximately 137 rkm in length and its watershed encompasses approximately 2,098 $\mathrm{km}^{2}$, most of which is in the Yukon Delta National Wildlife Refuge (Harper 1997, Figure 1). It originates in the Kilbuck Mountains and flows to the northwest. The Fog River drains into the lower portion of the Tuluksak River and is the only major tributary. The Tuluksak River is a slow moving river for the majority of its length and is characterized by dense overhanging vegetation and cut banks. The lower portion of the river is characterized by low-gradient, silty substrate and turbid waters. A weir operated seasonally (June-August) by the USFWS is installed approximately 49 rkm from the mouth and is used to enumerate escapement of Chinook, chum, coho, pink, and sockeye salmon.

## Sample collection

Tuluksak River adult Chinook salmon were sampled in the summer of 2003 (candidate parents) and in the summers of 2007-2009 (offspring) at and above the weir (Figure 1, Table 1) in order to reconstruct a pedigree and examine trait heritability and variation in family size. Most of the sample collection was performed by staff operating the weir including members of the Village Of Tuluksak. Weir operations were supervised by Darryl Sipary with oversight by Steve Miller of FWS, Kenai Field Office. Fin tissue samples for genetic analysis were collected from 108 Chinook in 2003 ( 55 males, 53 females). These samples represented $7.1 \%$ of the 776 male and $18.4 \%$ of the female Chinook that returned in 2003. Fin tissues samples were taken from 1,077 Chinook in the summers of $2007(\mathrm{n}=350)$, $2008(\mathrm{n}=422)$, and $2009(\mathrm{n}=305$, Table 1). Individual fin tissue samples were stored in a 2 ml vial in $95 \%$ ethanol. Scales or otoliths for ageing were also collected from each fish sampled in 2007-2009. The 2007-2009 collections were taken from pre-spawn adults at the weir $(\mathrm{n}=765)$ and post-spawn adults above the weir $(\mathrm{n}=312)$. The project goal of sampling 1,000 individuals each year between 2007 and 2009 (3,000 individuals for the study) was not met because the average annual adult return for the three years of the study (2007-
2009) was 460 Chinook or $29.7 \%$ of the anticipated average annual return of 1,550 observed between 1991 and 2004.

Figure 1. Map of the Tuluksak River showing the past and present weir sites.

Scales (pre-spawn adults) and otoliths (post-spawn adults) were used to age fish (see below) and identify the 2003 cohort from other cohorts in each of the three years. Because cohort ID was not possible until after the samples were collected, some samples taken each year (the other cohorts) were not used in this study. However, the information from these samples was used in other ways to complement ongoing monitoring and research. For example, the samples collected above the weir from post-spawn adults provided a rare opportunity to document the spatial distribution of spawners over a three year period.

Table 1. Sample summary for Tuluksak River Chinook salmon (2003, 2007-2009). Pre-spawn and post-spawn samples were taken at and above the weir, respectively. The column "2003 cohort analyzed" include only individuals from the 2003 cohort sample that were genotyped for 14 or more loci.

## Phenotypic data: Age, sex, and length

Age of adults was determined from scales and otoliths using standard methods (Koo 1962; Jearld Jr. 1983). The scales were processed by the Alaska Department of Fish and Game and the otoliths were processed by Dr. Chris Zimmerman, U.S. Geological Survey. Standardization of the two methods was performed by comparing scales and otoliths from fish sampled and tagged at the weir and recovered above the weir after spawning. Sex was determined by observation of external sex traits (Miller and Harper 2011). The length of all individuals was measured to the nearest 5 mm from the mid-eye to the fork of the caudal fin (MEF). The length of most individuals was measured to the nearest 5 mm from the mid-eye to hypural plate (MEH). Phenotypic data for the 392 samples from the 2003 cohort and the 108 samples from the 2003 adult return are included in Appendices 1 and 2, respectively.

## Genetic data

Seventeen microsatellite loci (Table 2) were used to genotype 500 individuals including the 2003 cohort samples ( $\mathrm{n}=392$ ) identified by scale/otolith analysis (Table 1) and the candidate parent sample from the 2003 adult return ( 55 males, 53 females).

Total genomic DNA was extracted from the fin tissue ( $\sim 25 \mathrm{mg}$ ) using proteinase K with the Dneasy ${ }^{\text {TM }}$ DNA isolation kit (Qiagen Inc. Valencia, CA), quantified with fluorometry and diluted to a standard concentration. An MJResearch DNA Engine ${ }^{\circledR}$ thermal cycler was used to perform polymerase chain reactions (PCR) in $10 \mu \mathrm{l}$ volumes; general conditions were: 2.5 mM MgCl 2 ,

1 X PCR buffer ( 20 mM Tris- $\mathrm{HCl} \mathrm{pH} 8.0,50 \mathrm{mM} \mathrm{KCl}$ ), $200 \mu \mathrm{M}$ of each dNTP, $0.40 \mu \mathrm{M}$ fluorescently labeled forward primer, $0.40 \mu \mathrm{M}$ unlabeled reverse primer, 0.008 units Taq polymerase, and $1 \mu 1$ of DNA ( $30 \mathrm{ng} / \mu \mathrm{l}$ ). Standard thermal cycling conditions were: initial denaturation cycle of $94^{\circ} \mathrm{C}$ for 3 min , followed by $94^{\circ} \mathrm{C}$ for $1 \mathrm{~min}, 50-62^{\circ} \mathrm{C}$ for 1 min (locusspecific annealing temperature), $72^{\circ} \mathrm{C}$ for 1 min , with a final single cycle of $72^{\circ} \mathrm{C}$ for 10 min . One $\mu 1$ of PCR product was electrophoresed and visualized with the Applied Biosystems 3730 Genetic Analyzer utilizing a polymer denaturing capillary system. Microsatellite allele sizes were estimated and scored by the computer program GeneMapper® version 4.0. Applied Biosystems GeneScan ${ }^{\text {TM }}-600$ LIZ® size standards, $20-600$ bases, were loaded in all lanes as an internal lane standard. All scores were verified manually. Alleles were scored by two independent researchers, with any discrepancies being resolved by replicating the analysis for the samples in question and repeating the double scoring process until scores matched. The multilocus microsatellite genotypes were stored in an Excel ${ }^{\mathrm{TM}}$ (Microsoft) spreadsheet prior to data analysis. The database software Access ${ }^{\mathrm{TM}}$ (Microsoft) was used for long term storage and archiving of the genetic data.

## Objective 1

## Pedigree reconstruction

To address objective 1 we first reconstructed a molecular pedigree from the Tuluksak River Chinook salmon genotypes (17 polymorphic loci) collected between 2003 and 2009. We compared a pedigree reconstructed with the program FRANz (Riester et al. 2009) with a pedigree reconstructed with the program Colony 2.0 (Wang 2004). Whereas Colony uses a likelihood algorithm to assign parentage based on the genotypes alone, FRANz uses a Bayesian framework and Metropolis-Hastings coupled Markov Chain Monte Carlo (MCMC) algorithm to assign parentage based on phenotypic data (age, lifespan) as well as genotypes. For this analysis, FRANz and Colony reconstructed nearly identical pedigrees, but FRANz assigned a few more parents than did Colony with high posterior probabilities of correct assignment. Consequently, we used the pedigree generated by FRANz for quantitative genetic analysis. Genotyping error was estimated at $<1 \%$ for each locus; genotyping failure per locus ranged from 0 to $3.8 \%$.

## Heritability estimates

We used an animal model to estimate the heritabilities of length (length.mef) and total age at maturation (age.total) from the pedigree data (total age and SW age are equivalent in variation here because FW age is fixed for these Chinook salmon). The animal model explicitly incorporates the breeding value of each individual (i.e., an individual's contribution to the trait phenotype in a population, measured as the deviation of its progeny from the population mean) as a random factor to estimate genetic (co)variance and heritability for traits by regressing phenotypes on breeding values (Wilson et al. 2010). An individual's breeding value for a phenotype is estimated from its trait covariance with those of its relatives. We applied the Bayesian approach incorporated in the R package MCMCglmm ("Markov Chain Monte Carlo generalized linear mixed models"; Hadfield 2010) to evaluate the phenotypes in the pedigree. For length we used a proper, weakly informative prior based on half the phenotypic variance. For age we used a parameter-expanded Cauchy prior with scale $=25$. Length was evaluated as a continuous trait, and total age (age-at-maturation) as an ordinal (multiple threshold) trait. The model incorporated adult sex as a fixed factor, so the estimates of heritability are conditioned on sex. Each analysis involved a single MCMC chain that was evaluated for convergence by inspection of the traces, posterior densities, and to ensure that the lag autocorrelation $<0.05$. The $95 \%$ credible intervals for each estimate were obtained from the posterior densities.

The MCCglmm estimates obtained from the Colony pedigree were statistically indistinguishable from those obtained from the FRANz pedigree and are not reported here.

## Objective 2

## Family size evaluation

To address objective 2 we evaluated the number of adult progeny assigned to the 55 males and 53 females sampled in 2003. The distribution of family size $(k)$ was evaluated by computing the index of variability $R_{k}=v(k) /(\bar{k})$ where $v(k)$ and $\bar{k}$ are the mean and variance of $k$. If survival is random, then $v(k) \cong \bar{k}$ and $R_{k}$ is (Crow and Morton 1955). We followed the protocol of Hedrick et al. (1995) and computed $R_{k}$ for males and females. The resulting $R_{k}$ estimates were
compared to 1 (the expectation when family survival is random). In addition, the distribution of family size for each sex was tested for goodness-of-fit to a Poison distribution (Sokal and Rohlf 1995).

Because the run size and consequently sample size of the 2003 cohort was smaller than anticipated in the project proposal and because the evaluation of the distribution of family size did not indicate family survival deviated from random expectation, we did not test if family size was related to the size (length) of the parent.

## RESULTS:

## Genotyping, genetic diversity, and phenotypic data

Of the 392 samples from the 2003 cohort, 309 were genotyped for 14 or more loci and were used in the analysis (Table 1). Of the 83 samples that were not genotyped for at least 14 loci all were taken from post-spawn carcasses. All candidate parents ( 55 males and 53 females) from the 2003 adult return were genotyped for 14 or more loci.

The 17 loci exhibited relatively high levels of genetic diversity. The estimated number of alleles per locus ranged from five to 58 and averaged 24.2. The estimated heterozygosity ranged from 0.10 to 0.90 and averaged 0.80 (Table 2).

The average age-at-maturity for the 392 samples from the 2003 cohort was $5.0 \mathrm{y} / \mathrm{o}$. The average age-at-maturity for the 108 samples from the 2003 adult return was $5.4 \mathrm{y} / \mathrm{o}$. The average length of adults ranged from 508.1 mm ( $4 \mathrm{y} / \mathrm{o}$ females from the 2003 cohort) to 893.8 mm ( $7 \mathrm{y} / \mathrm{o}$ females from the candidate parents (2003 return, Table 3).

Table 2. Estimated number of alleles (A) and heterozygosity ( He ) for 17 microsatellite loci in Tuluksak River Chinook salmon. These estimates were derived using the 309 samples from the 2003 cohort and the 108 samples from the 2003 adult return.

## Objective 1

## Pedigree reconstruction

Using the program FRANz, 49 of the 309 adult offspring (15.9\%) were assigned at least one parent sampled from the 2003 return (Table 4).

Table 4. Reconstructed pedigree for adult Chinook salmon that returned to the Tuluksak River in 2003 and their adult offspring that returned in 2007, 2008, and 2009. The pedigree was generated using the computer program FRANz. Year of return for each sample is denoted by the first two numbers following "ktul". The asterisk denotes the offspring for which both a male and female parent were identified. Phenotypic data for parents and offspring can be found in Appendices 1 and 2.

Forty eight offspring were assigned to a single parent: 40 offspring to a female parent and eight offspring to a male parent. One offspring was assigned both a male and female parent. Seven of the 55 males ( $12.7 \%$ ) and 24 of the 53 females ( $45.3 \%$ ) sampled in 2003 were assigned offspring. The sample of males and females from 2003 represent $7.1 \%$ and $18.4 \%$, respectively, of the total 2003 return. The number of offspring assigned to a single parent ranged from 1 to 5 .

## Heritability estimates

The values and precision of the estimates of heritability derived from the R package
MCMCglmm are summarized in Table 5 and in Figures 2-3. The heritability estimate for length (mid-eye to fork of caudal fin, MEF) was $0.240(95 \%$ credible interval $=0.077-0.708$, Figure 2). Sex had a significant ( $\mathrm{P}<0.05$ ) effect on variation in length (males shorter than females), so the heritability estimate for length was conditioned on the fixed effect of sex. The heritability estimate for age-at-maturation was not greater than zero (Table 5). The plots in Figure 3 show the problems with the traces and posterior densities for heritability of this trait and indicate that heritability of age-at-maturation could not be reliably estimated as an ordinal trait with our pedigree data. Because of this problem, we adopted an alternative approach to estimate the heritability of total age as a dichotomous "threshold" trait (ages 4-5 vs. ages 6-7) by converting the threshold value to an underlying continuous liability value using the simple method described by Dempster and Lerner (1950). Using that method the estimate for heritability of "liability" of age at maturation was 0.238 ( $95 \%$ credible intervals $0.077-0.708$, Figure 4). The effect of sex on variation in age at maturation was also significant $(\mathrm{P}<0.05)$ with males younger than females, so the heritability estimate for age was conditioned on the fixed effect of sex.

Table 5. Heritability estimates for length (mid-eye to fork of caudal fin, MEF) and age-at-maturation for Tuluksak River Chinook salmon.

|  |  | $95 \%$ Highest Posterior Density interval |  |
| :--- | :---: | :---: | :---: |
| Trait | Posterior mode of <br> heritability estimate | lower | upper |
| Length (MEF) | 0.240 | 0.077 | 0.708 |
| Age-at-maturation | $<0.001$ | $<0.001$ | 0.001 |
| "liability" of age- | 0.238 | 0.097 | 0.975 |
| at-maturation |  |  |  |

Estimated using a bivariate animal model, the phenotypic correlation between length and age was highly positive $(+0.829,95 \%$ confidence interval $=0.792-0.859)$. We could not estimate the genetic correlation between the traits reliably (the point estimate exceeded +0.995 , which we do not consider to be reasonable). This may not be surprising, given the weak pedigree. The lag autocorrelation (-0.010) suggested that the model might have to be run longer, and the results suggest that a more suitable prior may be necessary. We attempted a variety of weakly informative priors, including parameter-expanded priors, in exploring these analyses to estimate the genetic correlation, but in the end we concluded that the analyses are limited primarily by the low power of the pedigree determined by the small sample size and the low frequency of parental assignments. The constraint imposed by the shallow pedigree cannot be overcome by simply extending chain length or choosing an appropriate prior.

## Objective 2

## Family size evaluation

The number of offspring ranged from 0 to 5 for the candidate females and 0 to 3 for the candidate males (Table 6). Most individuals were assigned one or no offspring. The estimate of mean family size $\bar{k}$ was 0.774 and 0.164 for females and males, respectively (Table 7). The variance in family size was 1.179 and 0.251 for females and males, respectively. Although
the mean and variance estimates differed for females and males, the index of variability $\left(R_{k}\right)$ was approximately 1.5 for both sexes (Table 7). However, the value for the males should be viewed with caution given the small sample size for individuals with one or more offspring.

The $R_{k}$ estimates were larger than one (one is the expectation when family survival is random). Nonetheless, a chi-

Figure 3. MCMC estimates of heritability of age-at-maturation for Tuluksak River Chinook salmon. The left panel shows the trace of the estimate of heritability for the fitted model plotted over the $2,300,000$ iterations of the MCMC chain. The right panel shows the posterior density of the estimate of heritability for the fitted model.

Figure 4. The observed and expected distribution of the number of adult offspring for 53 female Chinook salmon sampled from the Tuluksak River in 2003.
square test of goodness-of-fit did not indicate $(0.10<\mathrm{P}<0.25)$ that the distribution of family size for females exhibited a significant departure from a Poison distribution (Figure 4). The test was not performed for the males because the sample size was too small.

Table 6. The number of Tuluksak Chinook salmon offspring from the 2003 cohort assigned to a sample of candidate parents ( 53 females, 55 males) from the 2003 adult return.

| Number <br> offspring | female | male |
| :---: | :---: | :---: |
| 0 | 29 | 48 |
| 1 | 13 | 6 |
| 2 | 7 | 0 |
| 3 | 3 | 1 |
| 4 | 0 | 0 |
| 5 | 1 | 0 |

Table 7. The index of variability $R_{k}=(v(k) /($ $\bar{k})$ ) of family size for the sample of candidate parents from the 2003 adult return of Tuluksak River Chinook salmon. $\bar{k}$ and $v(k)$ are the mean and variance of family size.

|  | Females | Males |
| ---: | ---: | ---: |
| $\bar{k}$ | 0.774 | 0.164 |
| $v(k)$ | 1.179 | 0.251 |
| $R_{k}$ | 1.523 | 1.531 |

## DISCUSSION:

## Objective 1

## Pedigree reconstruction

Pedigree information can provide valuable insight into the genetic basis of the variation observed in traits of interest to resource managers such as size, growth rate, and age-at-maturity. While there is a long history of evaluating pedigrees in of domestic plants and animals, reconstructing pedigrees for organisms in the wild is a challenging task (Pemberton 2008). Despite the
difficulties, there is much interest in evaluating wild pedigrees for species of conservation and management concern because these pedigrees better reflect the variety of environmental conditions that, in addition to genetics, influence the observed variation in traits in wild populations (Coyne and Beecham 1987, Pemberton 2008). Developments in molecular genetics and the advent of more sophisticated statistical tools have made the task of pedigree reconstruction more feasible for wild populations. Nonetheless, many issues, such as the size of the wild pedigree often cannot be controlled and can limit the conclusions that can be drawn from the pedigree information. Thus, wild pedigrees, especially for Pacific salmon, are rare.

In this study, we were able to identify for the first time and with a relatively high level of statistical certainty a partial two-generation pedigree for wild Chinook salmon from a river in western Alaska. Two methods of parentage assignment, the likelihood and Bayesian approaches, each provided similar results with high probabilities for the individual parent-offspring assignments. The corroborative results are indicative of the robustness of the partial pedigree and demonstrate that molecular genetic methods can identify first order relatives in western Alaska Chinook salmon populations. More importantly, the inferred parent-offspring relationships, combined with the phenotypic data on length and age-at-maturity provide the first estimates of the heritability of these traits in western Alaska salmon. On the other hand, the small size of the reconstructed pedigree limited the extent of the heritability analysis and likely contributed to the relatively low precision (broad credible intervals) for each heritability estimate. These limitations are discussed further in the section on heritability estimates below. Here we discuss factors contributing to the small number and size of the families uncovered in the partial pedigree.

Three factors most likely contributed to the small size of the reconstructed pedigree. First, the number of families in the reconstructed pedigree was limited by the size of the sample from the parent population (the 2003 adult return). That sample included 55 males and 53 females and represented $7.1 \%$ and $18.4 \%$, respectively, of the total number of each sex that returned in 2003. With that in mind, the fact that we only assigned parents for $15.9 \%$ (49 of 309) of the offspring from the 2003 brood year is not surprising. Many of the unassigned offspring are likely progeny of the unsampled portion of the 2003 adult return. Second, the fact that 29 of the 53 females ( $54.7 \%$ ) and 48 of the 55 males ( $87.3 \%$ ) were assigned no offspring despite the fact that close to $80 \%$ of the adult Chinook salmon were sampled during the years that the 2003 cohort returned
suggests that many individuals from the 2003 return did not contribute adult offspring to the population. The size of each family in the reconstructed pedigree was limited by the fact that the total annual return during each of the sample years $(2007,08,09)$ averaged just 460 fish, less than $30 \%$ of the annual average of 1,550 observed between 1991 and 2004. The small number of the Chinook salmon returning to the Tuluksak River continues to be a concern to the resource managers and is indicative of relatively poor survival of multiple cohorts including the 2003 broodyear sampled in this study. Finally, the size of each family was also limited by the fact that 83 of the 392 samples from the 2003 brood year were not included in the analysis because fewer than 14 of the 17 loci were identifiable. Most of these samples (78) were from carcass samples and it is believed that the failure to resolve most loci was due to poor tissue quality. Future studies should try, were possible, to acquire samples from mostly live samples. We were limited to sampling on a portion of live Chinook salmon at the Tulukak River weir in order to avoid excessive handling stress during the period when chum salmon (more numerous) are also present.

## Heritability estimates

The first objective was to estimate the heritability of adult size (length), growth rate, and age-atmaturation and the genetic covariance among these traits, in male and female Chinook salmon from the Tuluksak River. Despite the small size of the reconstructed pedigree we were able to partially meet this objective and obtain the first estimates of heritability for adult length and age-at-maturation in wild Chinook salmon from western Alaska. These results also add to the limited information available on trait heritability in wild salmon in general. We detected modest estimates of heritability ( 0.240 and 0.238 for length and age-at-maturation, respectively) for wild Tuluksak River Chinook salmon using an animal model. In addition, the two traits showed high and positive phenotypic correlation, but the genetic correlation between them could not be reliably estimated from the molecular pedigree. These heritability results indicate both traits have detectable genetic variation in this population although the values are lower than those reported by Hard (2004) for a hatchery population of Chinook salmon (heritability of length $=$ 0.34 , heritability of age $=0.35$ ) in Puget Sound, Washington. Given the relatively low precision (broad credible intervals) for each estimate in this study (Table 5) we cannot conclude that these heritability values are significantly lower than those reported by Hard (2004), however these new values do provide locally derived estimates from a wild population to use in future studies on
issues such as the influence of gear selectivity on adult size (e.g., Bromaghin et al. 2011). In a broader context, the results here suggest efforts to estimate heritability in other western Alaska populations would be productive as even a small pedigree can provide some information. Unfortunately, the small and incomplete pedigree limited the analysis and we were unable to assess growth rate, the genetic covariance among traits, and gender differences in heritability. While we demonstrated a phenotypic correlation between length and age-at-maturation, the test result for a genetic correlation was found to be unrealistically high ( +0.995 ). We attempted to improve the pedigree by rerunning the 78 carcass samples that did not provide adequate genotype information. We did this at least three times before concluding that these individuals were not useable. We also attempted additional Bayesian analyses involving chains of different lengths and different types of uninformative priors to maximize the information content of the pedigree. However, the results did not change. We concluded that a larger pedigree will be needed to more completely address objective one and provide more precise estimates of the heritability of length and age-at-maturity. We feel this can be accomplished by sampling the parent year more thoroughly (preferably close to $100 \%$ ) for a relatively small population in a river like the Tuluksak or the Tatlawiksuk in the Kukskokwim River drainage. Given the value but very limited amount of information on heritability and family size variation in wild salmon populations, and the availability of weirs on some tributaries of the Kuskokwim River, we feel further work that builds on the results of this study should be pursued

## Objective 2

## Family size evaluation

The second objective was to determine if the variation in family size of Tuluksak River Chinook salmon is random, and if not, determine if family size is related to size of adult parent. While previous studies have revealed a genetic basis for differences in family survival (Geiger et al. 1997; Hard et al. 2000) the evaluation of family size in the present study was equivocal. On one hand the estimates of the index of variation $\left(R_{k}\right)$ were larger than one (one is the expectation when family survival is random) for both male and female parents. On the other hand the chisquare test of the distribution of family size for female parents indicated the variation in family
size was not significantly different from random expectations (the test was not performed for males because the sample size was too small). These results did not support evaluating if family size is related to the size of the adult parent. As with the analysis of heritability, we feel the lack of clarity in the evaluation of family size is due to the limitations of the small pedigree. Nonetheless, some trends in the pedigree are worth noting with regard to family survival and may warrant further investigation. In particular, it is noteworthy that $54.7 \%$ and $87.3 \%$ of the females and males, respectively, in the candidate parent sample of 108 fish were assigned no offspring. This is unlikely to reflect inadequate sampling of the offspring escapement since close to $80 \%$ of the adult Chinook salmon were sampled during the years that the offspring (the 2003 cohort) returned. Thus, the reconstructed pedigree suggests that many adults (and more males than females) in the 2003 return did not produce offspring that contributed to the escapement in 20072009. This is not entirely surprising for the males given the fact that the estimated male escapement in 2003 was 776 fish while the estimated combined escapement of the 2003 cohort (2007-2009) was 535 fish (Zabkar and Harper 2004; Plumb and Harper 2008; Miller and Harper 2009; Miller and Harper 2010). On the other hand, the estimated female escapement in 2003 was 288 fish. So, despite the fact that on average 1.86 fish (535/288) from the 2003 broodyear returned for every female that returned to the river in 2003, many females (our sample suggests over $50 \%$ ) did contribute to the next generation spawning population. For males, the fraction not contributing the next generation could be much greater (our results suggest over $80 \%$ ) which may indicate that when the population is heavily weighted toward males (the ratio of males to females was 3.4:1 in the 2003 adult return) many males may not spawn or spawn unsuccessfully. It seems less likely that failure to spawn or unsuccessful spawning contributed to the lack of progeny for many of the females. However, little is known about Chinook salmon spawning in the Tuluksak River and subsequent survival of the progeny in freshwater and the marine environment. The results here support the need for more investigation to more fully examine reproductive success and variance in family size. Additional pedigree studies could provide valuable insight into reproductive success and help better establish if the offspring returns represent a relatively small number of the parental returns. As stated above for the heritability analysis, these studies should attempt to more fully sample the parent population.

## DELIVERABLES:

The following deliverables disseminate the findings from this study: 1) a final report and eight progress reports available through the AYKSSI program or from the authors, 2) two oral reports describing preliminary results presented at the annual Kuskokwim interagency meeting in 2010 and 2011, 3) genetic data (genotypes and allele frequencies) in Excel (Microsoft Office version 11) spreadsheets available from the authors, 4) phenotypic data (sex, age, and length) for each sample in an Excel (Microsoft Office version 11) spreadsheet available from the authors, 5), a manuscript in preparation for submission to a peer-reviewed journal.

## PROJECT DATA:

Genetic and phenotypic data are archived in Excel (Microsoft Office version 11) spreadsheets available from the authors (Conservation Genetics Laboratory, U.S. Fish \& Wildlife Service, 1011 East Tudor Road, Anchorage, Alaska, USA 99503. ph: (907) 786-3858, email: jeffrey olsen@,fws.gov).

## ACKNOWLEDGEMENTS:

Funding for this study was provided by the Arctic Yukon Kuskokwim Sustainable Salmon Initiative through project numbers 45493, 45566, 45059, and the US Fish and Wildlife Service (USFWS) Region Seven Conservation Genetics Laboratory. Tissue samples and phenotypic data were gathered by crews operating the USFWS weir on the Tuluksak River including Darryl Sipary and residents from the Village of Tuluksak. Ora Schlei conducted the laboratory analysis including genotyping. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the USFWS.

## PRESS RELEASE:

Heritability expresses the extent to which a given trait is determined by parental genes. It also reflects the potential for a trait to evolve from selection. In the context of a gillnet fishery that captures fish a certain size and age, the potential for the fishery to, over time, alter these traits will depend in part on the heritability of size and age in the target population. Because many Chinook salmon in the Kuskokwim River are harvested using "large mesh" (8 inches or larger) gillnets that preferentially capture older and larger fish, there is interest in determining if this selective fishery has a population-level impact on traits such as adult size and age. Few heritability estimates exist for these traits in Chinook salmon and those that do exist are mostly from hatchery populations in the Pacific Northwest. The study "Heritability of traits in wild Chinook salmon" examined heritability of adult size (length) and age-at-maturity in wild Chinook salmon from the Tuluksak River in the Kuskokwim River watershed. Adult salmon returning to the Tuluksak River in 2003 and their offspring returning in 2007, 2008, 2009 were sampled at and above a weir located approximately eight miles from the river mouth. These samples were analyzed using genetic markers to identify parents and their offspring and reconstruct for the first time a partial two-generation pedigree from a wild Chinook salmon population in western Alaska. The inferred parent-offspring relationships, combined with data on adult length and age-at-maturity provide the first estimates of the heritability of these traits in western Alaska salmon. These estimates of heritability ( 0.240 and 0.238 for adult length and age-at-maturation, respectively) indicate both traits have detectable genetic variation in this population although the values are lower than those reported for a hatchery population of Chinook salmon in Puget Sound, Washington. While we could not conclude that these heritability estimates are significantly lower than those reported for the hatchery populations, these new values do provide locally derived estimates from a wild population to use in future studies on the influence of gear selectivity. The pedigree was also used to evaluate if offspring with large parents have higher survival than offspring with small parents. However due to the small size of the pedigree in this study the results of this evaluation were not conclusive. Given the value but very limited amount of information on heritability and family size variation in wild salmon populations, and the availability of weirs on some tributaries in the Kuskokwim River, we feel further work that builds on the results of this study should be pursued.

## APPENDICES:

Appendix 1. Sample data for the 2003 cohort. MEF and MEH are the length estimates to nearest 5 mm from the mid-eye to the fork of the caudal fin (MEF) and from the mid-eye to hypural plate (MEH). Freshwater (FW) and saltwater (SW) age were derived from scales (live samples) or otoliths (carcasses).

| Sample ID | Date | live carcass | Sex | MEF | MEH | FW age | SW age | Total age |

Appendix 1. Sample data for the 2003 cohort. MEF and MEH are the length estimates to nearest 5 mm from the mid-eye to the fork of the caudal fin (MEF) and from the mid-eye to hypural plate (MEH). Freshwater (FW) and saltwater (SW) age were derived from scales (live samples) or otoliths (carcasses).

Appendix 1. Sample data for the 2003 cohort. MEF and MEH are the length estimates to nearest 5 mm from the mid-eye to the fork of the caudal fin (MEF) and from the mid-eye to hypural plate (MEH). Freshwater (FW) and saltwater (SW) age were derived from scales (live samples) or otoliths (carcasses).
